Received: April 20, 2005; In Final Form: May 28, 2005

X-ray absorption fine structure combined with X-ray fluorescence spectrometry was applied to various V-TiO\(_2\) hybrid samples. Emitted V K\(\alpha_1\) fluorescence from the sample was selectively counted by using a high-energy-resolution (0.4 eV) spectrometer equipped with a Ge(331) crystal. Two advantages of this method, extremely high signal/background ratio and the compatibility of measurements in the atmosphere of reaction gas (in situ study in relation to heterogeneous catalysis), were effective at the V K-edge. Structure transformation of the V sites was spectroscopically followed for the V/TiO\(_2\) catalyst. The monooxo tetrahedral vanadate site was demonstrated to exist at 473 K. It transformed into dispersed species of 5-fold coordination in ambient air and further into polymeric VO\(_x\) species in 0.85 kPa of water at 290 K. In the presence of 3.2 kPa of 2-propanol, dissociative adsorption of 2-propanol on the dispersed V species was strongly suggested at 290–473 K. In situ structure changes of V sites on TiO\(_2\) were reported by means of XAFS for the first time. The V\(^V\) sites for the V/TiO\(_2\) catalysts were essentially identical with those for V supported on mesoporous (high-surface-area) TiO\(_2\) and V-TiO\(_2\) sample prepared by the sol–gel method. However, predominant V\(^IV\) sites were found for mesoporous V–TiO\(_2\). The V\(^IV\) sites substituted on the Ti sites of TiO\(_2\). Emitted V K\(\alpha_1\) fluorescence associated with the V K-edge absorption. 8

In this paper, vanadium K-edge XAFS combined with high-energy-resolution XRF was applied to selectively monitor low concentrations of V on/in titanium oxide. Structure transformations of the V sites were spectroscopically followed in the presence of 2-propanol or water in relation to catalysis. Advantage (2) was effective for this system7,8 because Ti K\(\alpha_1\) (4510.8 eV), Ti K\(\beta_{1,3}\) (4931.8 eV), Ti K\(\beta_5\) (4962.3 eV), and/or diffracted X-ray from V+TiO\(_2\) (VO\(_x\)-TiO\(_2\)) sample were effectively suppressed by detecting the V K\(\alpha_1\) (4952.2 eV) with \(\Delta E\) of 0.4 eV using a fluorescence spectrometer. 1,8 The feasibility of advantage (3) at the V K-edge is discussed to study the preedge peak feature originating from V 1s \(\rightarrow\) 3d electronic transition in more detail. Recently by the measurements of iron K\(\beta_{1,3}\)-detected XANES (X-ray absorption near-edge structure), the Fe site symmetry was discussed based on more precise separation of Fe K preedge peaks for Fe-ZSM-5 zeolites. 15 In an atmosphere of reaction gas, the only way to selectively monitor minor V sites on/in high concentrations of TiO\(_2\) matrix is selective, high-energy-resolution detection of V X-ray fluorescence associated with the V K-edge absorption. 8

Low concentrations (less than monolayer) of VO\(_x\) supported on TiO\(_2\) are good catalysts for the nitric oxide reduction with ammonia, 16 selective oxidation of naphthalene/\(\alpha\)-xylene to

Introduction

We have developed and applied a structural analysis technique, X-ray absorption fine structure (XAFS) combined with X-ray fluorescence (XRF) spectrometry, to heterogeneous catalysis and environmental chemistry. 1–11 The fluorescence spectrometer utilized was Rowland-type 1 and the energy resolution (\(\Delta E\)) was 1.1 eV at 8 keV including the contribution of beamline. 3 Three major advantages have been demonstrated. As advantage (1), this method enables a chemical/spin state-sensitive structural (both geometric and electronic) study for X-ray absorbing element. 2–4,12,13 The chemical shifts of emitted X-ray fluorescence were discriminated by high-energy-resolution XRF spectrometry. Advantage (2) of this method is a spectral feature of ultimately high signal/background (S/B) counts ratio. 5–11 By suppressing the predominant background counts originating from high concentrations of element(s) in sample, weaker signals originating from lower concentrations of element were observed selectively. Advantage (3) is to eliminate the core-hole lifetime broadening effects by detecting the X-ray fluorescence with a smaller energy band than the core-hole lifetime width of the X-ray absorbing K or L shell. 2,6,10,13,14

*Estimated values assuming all the V species dispersed on TiO₂ surface.

phthalic anhydride,¹⁷,¹⁸ and selective oxidation of butane to maleic anhydride.¹⁹ The V site structures under these catalytic reaction conditions are still controversial.²⁰ The spectroscopic (technical) difficulties in obtaining information of V sites on TiO₂ compared to on SiO₂ or Al₂O₃ were reported for XAFS.²¹ Raman (strong scattering from TiO₂),²¹ and ultraviolet (UV)—visible (strong photon absorption by TiO₂) measurements.²² Despite the technical difficulties, site structures of monomeric phthalic anhydride, ¹⁷,¹⁸ and selective oxidation of butane to V₂O₅,¹⁷ were studied in relation to catalysis by using Raman,²¹ UV–visible spectroscopies,²² and density functional theory (DFT) calculations.²³,²⁴ The phase similar to an epitaxial V₂O₅-(010) layer was reported to prevail over TiO₂ when the V loading was greater than 4 wt %.²⁵ The V K-edge XAFS was measured for 3.9 wt % of V on TiO₂ in the transmission mode.²⁹–³¹

Among various spectroscopic techniques, XAFS gives direct information on geometric and electronic structures of the V center. Thus in this paper, 0.6–10.4 wt % of V site transformations on/in TiO₂ are studied in relation to catalysis by using modern highly brilliant synchrotron X-rays and V Kα₁/XAFS combined K-edge XAFS.

Experimental Section

Sample Preparation. TiO₂ (Degussa P25; specific surface area 60 m² g⁻¹, anatase/rutile phase ≈ 95/5) was impregnated with V trisopropoxide oxide (1) in the 2-propanol solution. These catalysts are denoted as impregnated V/TiO₂. The V contents were varied between 1.0 and 3.0 wt % on the V metal basis (1.8–5.4 wt % on the V₂O₅ basis).

Mesoporous V–TiO₂ samples were prepared from compound 1, Ti tetraisopropoxide (2), and dodecylamine (3). An aqueous solution was maintained at 333 K for 6 days and filtered. The obtained powder was heated at 453 K for 10 days, and then washed with p-toluene sulfonic acid in ethanol. The V contents were varied between 0.6 and 10.4 wt %. The molar ratio of V/Ti was listed in Table 1 for each sample. The specific surface area was 1200 m² g⁻¹ for the sample of 0.6 wt % V. Based on the X-ray diffraction (XRD) analysis, the spacing of its mesopores was ≈30 Å and wormhole-like structure prevailed rather than ordered mesoporous crystalline structure.²² Mesoporous TiO₂ prepared from compounds 2 and 3 in a similar procedure was impregnated with compound 1 in the 2-propanol solution. This sample is denoted as V/mesoporous TiO₂. Another reference sample was prepared from compounds 1 and 2 in the absence of compound 3, in a similar procedure to that for mesoporous V–TiO₂. This sample is denoted as sol–gel V–TiO₂. All of dried powders were calcined in air at 473 K and pressed into a disk of diameter 20 mm in ambient air.

V metal foil (25 μm thickness, Aldrich), Cr₂O₃, NH₄VO₃, V₂O₅, VO(SO₄)₂·3H₂O, and V₂O₅ (Special or First Grade, Wako) were used as received. Mn₀.₆₇V₁₈M₀₂O₄₅ and Mn₁₈V₁₈₃CrVO₄ crystallites were synthesized by the solid-state reaction of MnV₂O₆ with MoO₃ at 873 K.³³ The powders of these chemicals were diluted with boron nitride to 1.0 wt % V, mixed thoroughly using mortar and pestle, and pressed into a disk of diameter 20 mm.

V Kα₁ Emission and K-Edge XAFS Spectra Measurements. For the series of V–TiO₂ samples in each fresh state, the V Kα₁ emission spectrum was measured with the excitation energy set at 5484.1 eV using a homemade high-energy-resolution fluorescence spectrometer at beamline 7C of KEK-PF. The storage ring energy was 2.5 GeV and the ring current was 390–270 mA. A Si(111) double-crystal monochromator was used. The X-ray beam was focused and fully tuned. The X-ray fluorescence from the sample was analyzed by using a spectrometer of Rowland radius set to 180 mm equipped with a Johansson-type Ge(331) crystal (50 × 30 mm², Saint-Gobain) and a scintillation counter (SP-10, Oken). Their positions were controlled by PC on the micrometer level. After the exit of beam duct, the entire beam path was purged with helium gas except for the inside of the I₀ ion chamber (Oken; N₂:He = 3:7).³⁴

The fluorescence spectrometer was tuned to the peak top for each sample and the V K-edge XAFS spectrum was measured at 290 K. The scan step of the monochromator was ~6.9, ~0.25, and ~2.75 eV in the energy range 5130–5440, 5440–5545, and 5545–6015 eV, respectively. The dwell time of each data point was 60–200 s. The energy positions of the monochromator and the fluorescence spectrometer were reproduced within ±0.1 and ±0.2 eV, respectively. The V Kα₁ and V K rising-edge energies of the V metal were calibrated to 4952.20 and 5463.9 eV, respectively.³⁴ The XAFS spectra for standard inorganic V compounds were measured in transmission mode at 290 K using an I₀ ion chamber purged with N₂ instead of the high-energy-resolution fluorescence spectrometer.

In situ V Kα₁-detecting XAFS measurements for V/TiO₂ catalyst were performed at beamline 15XU of SPring-8.³⁵ The storage ring energy was 8.0 eV and the ring current was 89–53 mA. A Si(111) double-crystal monochromator was used. The planar undulator gap and the ΔΩ of the second crystal of the monochromator (rocking curve) were optimized to maximize the beam flux at each data point of the XAFS spectrum scan. The scan steps and the setup and measurement conditions of the fluorescence spectrometer were essentially the same as those for the measurements at KEK-PF. The fluorescence spectrometer was tuned to the top of the V Kα₁ peak and then the XAFS spectrum was measured. The dwell time of each data point was 10–60 s. The pressed disk of V/TiO₂ (1.0 wt % V) was introduced into a reaction cell made of stainless steel, equipped with two Be windows for incident and emitted X-rays, ceramic heater, water cooling path, gas supply, and a connection to a vacuum pump. The two Be windows of 100 μm thickness and 10 mm diameter were located to make an angle of π/2 projected from the sample at the center of the reaction cell. The sample temperature can be controlled between 290 and 673 K. The reaction cell was accommodated in our high-energy-resolution fluorescence spectrometer for spectral measurements. After the reaction cell was evacuated, 3.2 kPa of 2-propanol or 0.85 kPa of water was introduced.

XAFS Data Analysis. The XAFS data analysis was performed with the package XDAP (XAFS Services International) based on the works of M. Vaarkamp, H. Linders, and D.
For impregnated V/TiO$_2$ (Figure 1a, b), the rising edge appeared at 5480.8–5481.1 eV. Among data for reference inorganic V compounds (spectra g–l), the rising edge position for Mn$_{0.9}$V$_{1.0}$Mo$_{0.2}$O$_6$ (g) or NH$_4$VO$_3$ (i) was most close to the values for V/TiO$_2$. The spectrum for Mn$_{0.67}$V$_{1.33}$Mo$_{0.67}$O$_6$ (not shown) was essentially the same as that for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (g). Two broad peak features were observed in the postedge region (5489 and 5502 eV) at nearly equal intensity in spectra a and b. The preedge peak energy positions, width, and intensity were evaluated by the fit of the pseudo-Voigt function using KaleidaGraph version 3.6.4 (Synergy Software). The many-body reduction factor ($S_m$) was assumed to be equal for sample and reference. The goodness of fit was given as requested by the Committee on Standards and Criteria in X-ray Absorption Spectroscopy.

Results

**V K$_\alpha$ Emission Spectra.** The V K$_\alpha_1$ emission peaks for all V+TiO$_2$ samples appeared at 4951.5–4952.0 eV. The chemical shifts with respect to V metal were reported at −0.1, −0.3 to −0.4, and −0.5 to −0.6 eV for V$^{III}$, V$^{IV}$, and V$^V$ compounds, respectively. Hence, the V valence states in V+TiO$_2$ samples studied in this paper were IV and/or V.

**XANES of V/TiO$_2$.** Normalized V K-edge XANES spectra are shown in Figure 1. The intensity and energy positions for the preedge peak and rising edge were summarized in Table 3. For impregnated V/TiO$_2$ (Figure 1a, b), the rising edge appeared at 5480.8–5481.1 eV. Among data for reference inorganic V compounds (spectra g–l), the rising edge position for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (g) or NH$_4$VO$_3$ (i) was most close to the values for V/TiO$_2$. The spectrum for Mn$_{0.67}$V$_{1.33}$Mo$_{0.67}$O$_6$ (not shown) was essentially the same as that for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (g). Two broad peak features were observed in the postedge region (5489 and 5502 eV) at nearly equal intensity in spectra a and b. The two peak energy positions were similar to 5489 and 5503 eV for V/TiO$_2$ (3.9 wt % V; f) and 5490 and 5504 eV for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (g). Mn$_{1-x}$V$_{2-x}$Mo$_{2}$O$_6$ (0 ≤ x ≤ 1) consists of a Brannerite-type crystal structure. The V site was coordinated by two nearer O atoms (1.661–1.693 Å) and three farther O atoms (1.913–2.151 Å) when the x value was 0.53 (Table 2). A shoulder peak appeared at 5486 eV in Figure 1b. The postedge patterns for CrV$^V$O$_4$ (h), NH$_4$V$^V$O$_3$ (i), and V$^V$O$_5$ (j) were qualitatively different from those of spectra a and b.

A 1s → 3d preedge peak appeared at 5468.3–5468.6 eV for V/TiO$_2$ (Figure 1 and Table 3) at similar energy positions to those for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$, CrVO$_4$, and NH$_4$V$^V$O$_3$ (5468.2–5468.6 eV). However, the peak intensity for spectra a and b was only 62–70% of that for CrVO$_4$ (h). This difference suggests that the V site symmetry for V/TiO$_2$ (1.0–3.0 wt % V) was higher than tetrahedral for the V sites of CrVO$_4$ and NH$_4$V$^V$O$_3$. The preedge peak intensity was comparable between V/TiO$_2$ (Table 3, entries a and b) and Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (Table 3, entry g) within the difference of 20%.

**XANES of Mesoporous V$^V$–TiO$_2$, V$^V$/Mesoporous TiO$_2$, and Sol–Gel V$^V$–TiO$_2$.** For mesoporous V$^V$–TiO$_2$ (0.6 wt % V), the rising edge position shifted by 1.0–1.3 eV toward the lower energy side compared to data for V/TiO$_2$ (Table 3, entries a–c). This shift suggested the dominance of V$^{IV}$ and V$^V$ sites for V$^V$–TiO$_2$ and impregnated V/TiO$_2$, respectively, based on rising edge energy positions for standard V$^V$ (Table 3, entries k and l) and V$^V$ (Table 3, entries g–j) compounds.
Two broad peak features were observed at 5487 and 5505 eV in the postedge region, shifted by ±2 eV from the values for V/TiO$_2$.

The XAFS spectrum for mesoporous V$_2$O$_4$ was identical with that for mesoporous V$_2$O$_4$-3H$_2$O.

The Ti K-edge spectrum for mesoporous TiO$_2$ was smaller than those for V/TiO$_2$.

The XANES spectrum for mesoporous V$_2$O$_4$ that contains more V content (10.4 wt % V) by 20 times is depicted in Figure 2b.

The spectrum was very similar to that for V/TiO$_2$.

**Figure 2.** V K-edge XANES spectra for mesoporous V$_2$O$_4$ samples combined with high-energy-resolution XRF. V contents: 0.6 (a) and 10.4 wt % (b). Reference Ti K-edge XANES measured in transmission mode for mesoporous TiO$_2$ (c). The energy of spectrum c was shifted 10.4 eV from the values for V/TiO$_2$. Although the rising edge position for V$_2$O$_4$-3H$_2$O was identical with that for mesoporous V$_2$O$_4$, the postedge pattern was totally different between the two (Figure 1c,k). The postedge pattern for TiO$_2$ (l) was relatively similar to that for spectrum c. The Ti K-edge spectrum for mesoporous TiO$_2$ was compared to V K-edge spectra by shifting the former energy scale by +499.8 eV to adjust the preedge peak energy. The phase parameters are similar between Ti and V. The rising edge energy position and postedge pattern were very alike those of V K-edge for mesoporous V$_2$O$_4$ (Figure 2a,c).

The preedge peak intensity and energy position for VOSO$_4$.3H$_2$O and V$_2$O$_5$ were not comparable to those for mesoporous V$_2$O$_4$. The Ti K-edge XANES spectrum for mesoporous TiO$_2$ that contains more V content (10.4 wt % V) by 20 times is depicted in Figure 2b. The spectrum was very similar to that for V/TiO$_2$.

*a** Entries a–f were for XAFS spectra combined with high-energy-resolution XRF. Entries g–m were measured in transmission mode. † Entry l' was measured in fluorescence detection mode with a Lytle detector.

**Figure 3.** In situ V K-edge XANES spectra for V/TiO$_2$ (1.0 wt % V) combined with high-energy-resolution XRF: as prepared (a), in 3.2 kPa of 2-propanol at 290 (b) and 473 K (c), and mesoporous V$_2$O$_4$ (0.6 wt % V) for comparison (d).

Mesoporous V$_2$O$_4$ (2.3 eV) was smaller than those for V/TiO$_2$ (2.5 eV). This implies that the V sites in mesoporous V$_2$O$_4$ are more statistically uniform compared to those in V/TiO$_2$ because the spectral measurement conditions for these samples were essentially the same. In summary, the local structure of predominant V$_{IV}$ species in mesoporous V–TiO$_2$ was more uniform and similar to that of Ti sites in mesoporous TiO$_2$.

The XANES spectrum for mesoporous V$_2$O$_4$ that contains more V content (10.4 wt % V) by 20 times is depicted in Figure 2b. The spectrum was very similar to that for V/TiO$_2$. For V/mesoporous TiO$_2$ and sol–gel V–TiO$_2$, the preedge, rising edge, and two postedge-region peaks appeared at 5468.5, 5481.1–5481.3, 5487–5488, and 5501–5504 eV, very close to those for impregnated V/TiO$_2$ (5468.3–5468.6, 5480.8–5481.1, 5489, and 5502 eV). Preedge peak intensities for V/mesoporous TiO$_2$ and sol–gel V–TiO$_2$ were 111–126% and 74–83%, respectively, compared to values for V/TiO$_2$ (Table 3). Thus, the V sites of these two reference samples were essentially the same as those of V/TiO$_2$.

**In Situ XAFS of V/TiO$_2$** In situ V K-edge XANES spectra in 3.2 kPa of 2-propanol were measured by selectively detecting the V K$_{α1}$ signals (Figure 3 and Table 4). The spectra measured at 290 and 473 K in the reaction cell were similar to...

\textsuperscript{a}Entries a–d were for XAFS spectra combined with high-energy-resolution XRF.

![Figure 4](image)

**Figure 4.** In situ V K-edge XANES spectra for impregnated V/TiO\textsubscript{2} (1.0 wt % V) combined with high-energy-resolution XRF: as prepared (a) and in 0.85 kPa of water at 290 (b) and 473 K (c). Data for NH\textsubscript{4}VO\textsubscript{3} were measured in transmission mode for comparison (d).

Each other (Figure 3b,c). The preedge peaks became weaker 34–38% and shifted toward the lower energy side by 0.6 eV with respect to the peak for fresh sample (Table 4). The rising edge energy position also shifted toward the lower energy side by 1.2–1.6 eV. The postedge broad peaks at 5489 and 5502 eV for fresh sample shifted to 5486 and 5501 eV in 2-propanol. The former peak became more intense than the latter (Figure 3b,c). The values of intensity, width, and energy position of preedge peak, rising edge energy position, and the two postedge broader peak positions for spectra of V/TiO\textsubscript{2} in 2-propanol (Table 4, entries b and c) were similar to corresponding values for mesoporous V–TiO\textsubscript{2} of 0.60 wt % V (Table 4, entry d, and Figure 3d).

In situ V K-edge XANES spectra for V/TiO\textsubscript{2} measured in 0.85 kPa of water are depicted in Figure 4. Representative data values are summarized in Table 5. At 290 K, the preedge peak negligibly changed compared to the fresh one, but the rising edge shifted toward the lower energy side by 0.9 eV and the intense postedge peak appeared at 5486 eV (Figure 4b). This V species is not identical with that postulated to exist in 2-propanol (Figure 3b,c) because the preedge peak intensities were different by 3.0–3.3 times (Table 4, entries b and c, and Table 5, entry b). At 473 K, the preedge peak was still negligibly changed. On the contrary, the postedge region qualitatively changed. The broad peak at 5506 eV became more intense compared to that at 5489 eV (Figure 4c). The most similar spectrum profile to this was found for NH\textsubscript{4}VO\textsubscript{3} (d). The transformation of V species corresponding to Figure 4a into 4c was reversible. A very similar spectrum to spectrum a was obtained when the sample for spectrum c was cooled to 290 K, evacuated, and exposed to ambient air.

EXAFS. V K\textsubscript{0}-detecting EXAFS spectra were measured for V/TiO\textsubscript{2} (1.0 wt % V) in 0.85 kPa of water at 473 K and mesoporous V–TiO\textsubscript{2} (10.4 wt % V). The background-subtracted EXAFS \(\chi\)-functions are depicted in Figure 5A (b and a, respectively) along with those for reference compounds, NH\textsubscript{4}VO\textsubscript{3} (c), VOSO\textsubscript{3}-3H\textsubscript{2}O (d), and Mn\textsubscript{0.9}V\textsubscript{1.8}Mo\textsubscript{0.2}O\textsubscript{6} (e). Best fits for filtered \(k\)-weighted \(\chi\)-functions of V/TiO\textsubscript{2} (B) and mesoporous V–TiO\textsubscript{2} (C) both in \(k\)-space (1) and \(R\)-space (2; the magnitude and imaginary parts): (−) experiment and (−−) theory.

average V–O bond distance was shorter for mesoporous V–TiO2 (1.67 Å) than that for V/TiO2 in water at 473 K (1.86 Å).

Discussion

Advantages of V Kα1-Detecting XAFS. V Kα1-detecting V K-edge XAFS spectra were obtained for various fresh V+TiO2 samples (Figure 1). The application of this technique was extended to V/TiO2 catalyst in two kinds of reaction gas at elevated temperature (Figures 3–5). In addition to advantage (2) (see the Introduction section), selective V Kα detection is advantageous compared to selective Auger or secondary photoelectron detection derived from V sites by an electron energy analyzer because X-ray fluorescence-detecting XAFS is compatible with the presence of reaction gases.

In V K-edge XANES spectra, the preedge peak width is related to the core-hole lifetime width of $K + M_{\text{core}}$ (≈1.01 eV), the $\Delta E$ of the beamline, the energy splitting of the unoccupied V 3d multiplet to which the 1s electron can transit, and the peak energy variation due to the presence of some kinds of V sites in a sample. The last factor is negligible in the case of VOSO4•3H2O crystalline. A general trend exists that the width of the preedge peak decreased as the coordination number to V decreased (accordingly smaller 10Dq values) for standard inorganic V compounds (Tables 2 and 3). Thus, the latter two factors should be minimal for the spectra of VOSO4•3H2O, CrVO4, and NH4VO3. Their preedge peak widths were smallest (2.2–2.3 eV, Table 3). Therefore, the total energy width due to $\Delta E$ of the beamline and the latter two additional factors was estimated to 2.0 eV.

The V Kα1 emission peak width is related to the core-hole lifetime width of $K + L_1$ (1.26 eV),† the $\Delta E$ of the beamline and of fluorescence spectrometer, and the peak energy variation due to the presence of some kinds of V sites in sample. The smallest fwhm values for the V Kα1 peak were 2.4 eV for V metal and impregnated V/TiO2.†† If we assume the V 3d multiplet splitting effect (for vacant levels to which the 1s electron transits) on the V preedge peak width was negligible, the $\Delta E$ of our fluorescence spectrometer is estimated to 0.4 eV at 5 keV.

To apply advantage (3) (the Introduction section) at the V K-edge, the convolution of $\Delta E$ of the beamline and fluorescence spectrometer should be less than the core-hole lifetime width of vanadium K (1.01 eV). To satisfy this condition, the $\Delta E$ of the beamline should be less than 0.9 eV. Thus, advantage (3) was not effective in this paper. The fact is evident in Table 3 that the preedge peak widths for V Kα1-detecting XAFS using a fluorescence spectrometer (2.3–2.5 eV, a–e) were comparable to those for spectra measured in transmission mode (2.2–3.4 eV, g–l).

V Site Structure Transformations. Othof et al.‡‡ reported XANES for supported V samples over SiO2, Al2O3, ZrO2, and HfO2 under hydrated and dehydrated conditions. The V K-edge data were measured in conventional fluorescence detection mode.‡‡† Reported XANES profile changes before and after dehydration in dry air at 723 K for V/SlO2 (8.4 wt % V) and V/Al2O3 (5.6 wt % V) in ref 21 were similar to the change observed in this paper before and after the water (0.85 kPa) treatment at 473 K for V/TiO2 (1.0 wt % V) (Figure 4a,c). Postedge profile changes were remarkable in both cases.

Structural change by dehydration of V/TiO2 (0.6–2.2 wt % V) was studied using 51V NMR‡‡ and Raman.‡‡ Upon dehydration, transformation from 6-fold coordination polymeric vanadate (e.g. metavanadate) into dispersed tetrahedral monooxo vanadate was suggested. The site transformation from higher symmetry to tetrahedral was supported by DFT calculations‡‡‡ and ab initio calculations of V K-edge XANES spectra.‡‡ Spectrum profiles of Figure 4a and 4c were more similar to data for surface V site models of 5-fold and 4-fold coordination, respectively, calculated by ab initio calculations of XANES.‡‡ V Kα1-detecting EXAFS analysis demonstrated V–O bonds at 1.86 Å (average) with the coordination number of 3–4 rather than 5 (Table 6) for V/TiO2 in water at 473 K. Thus, the V sites of V/TiO2 in water at 473 K (Figures 4c, 5A-b, and 5B) are determined for monooxo (distorted) tetrahedral species (Figure 6b).

Monooxo tetrahedral V species were reported over SiO2, Al2O3, and TiO2 based on a V=O stretching Raman peak at $\approx1030$ cm$^{-1}$ in comparison with data for standard compounds (O=VX3 (X = halogens and alkoxides).‡‡ Jehng et al. reported the effects of water on the V site structure for V/TiO2 (0.56 wt % V) as a function of temperature using Raman spectroscopy.‡‡ In moisture, the peak at 1024 cm$^{-1}$ was observed between 623 and 723 K but it diminished between 393 and 443 K. This trend does not contradict with our results in Figure 4. Namely, (distorted) monooxo tetrahedral V species in spectrum c measured at 473 K in water transformed into the V species of higher symmetry until 290 K (spectrum a). Proposed V site transformation was illustrated in Figure 6 (b → a→ d).

The XANES spectrum for fresh V/TiO2 (Figure 1b) was measured inside the acrylic chamber of the fluorescence spectrometer purged with He gas; however, the sample was once exposed to ambient air before the measurement. The XANES was most similar to that for Mn1–xVx2–xMo2O6 (Figure 1g and 1h).
In situ V K-edge XANES for V/TiO$_2$ in 2-propanol (3.2 kPa) both at 290 and 473 K suggested higher coordination (higher symmetry) V sites (Figure 3bc). Hence, dissociative adsorption of the 2-propanol molecule on dispersed vanadate was suggested to form octahedral vanadate species (Figure 6c). Went et al. observed the reaction of V/SiO$_2$, V/Al$_2$O$_3$, and V/TiO$_2$ with ethanol by Raman. They discussed that with the addition of ethanol the cleavage of the V–OH bond proceeded when M = Si but simple adsorption of ethanol was proposed when M = Al and Ti.$^{29}$ The transformation proposed in Figure 6a,c is consistent with their discussion.

**Varieties of V Sites On/Inside TiO$_2$.** In the series of V+/TiO$_2$ samples, only the V sites of mesoporous V–TiO$_2$ were found to be at the V$^{IV}$ state and the local site structure was similar to that for Ti sites of mesoporous TiO$_2$ (Figure 2a,c). The V$^{IV}$ sites should be substituted on the Ti sites (Figure 6e). The reason is unclear why only the preedge peak intensity grew by 2.5 times (Figure 1g).

The extent of hydration for the V species of Figure 1b should be intermediate. When the V/TiO$_2$ sample was in 0.85 kPa of water at 290 K (Figure 4b), the dispersed vanadate species (Figure 6, a and/or b) was thoroughly hydrated to transform into surface polymerized species (d).$^{21,22,27,46,48}$ For V/TiO$_2$ in ambient condition, a higher ratio of polymeric vanadate versus dispersed tetrahedral monooxo vanadate was reported compared to the cases of V/SiO$_2$ and V/Al$_2$O$_3$ in ambient condition.$^{21}$ Hence, species a and d illustrated in Figure 6 may coexist for ambient V/TiO$_2$ (1.0–3.0 wt % V) in this study. Even if the V sites were the mixture, the V sites of 5-fold coordination should be dominant because the XANES spectra (Figure 1a,b) were most similar to that for Mn$_{0.9}$V$_{1.8}$Mo$_{0.2}$O$_6$ (Figure 1g).

**Conclusions.** V K$_{α_1}$-detecting K-edge XAFS spectra were measured for V/TiO$_2$ (1.0–3.0 wt % V), mesoporous V–TiO$_2$ (0.6–10.4 wt % V), V/mesoporous TiO$_2$ (1.0 wt % V), and sol–gel V–TiO$_2$ (2.0 wt % V). Owing to the selective detection of V K$_{α_1}$ fluorescence associated with the V K-edge absorption with the energy resolution of 0.4 eV, spectra of extremely high S/B ratio were obtained. The data were free from the effects of high concentrations of Ti and measurements in the presence of 3.2 kPa of 2-propanol or 0.85 kPa of water were also enabled. These gases are reactant and product in the catalysis (selective reduction of NO and selective oxidation to phthalic hydrate and maleic anhydride).

Dispersed 5-fold coordination vanadate and/or surface polymeric V$^{V}$ species of 5-fold coordination were found for V/TiO$_2$, once exposed to ambient air. In the presence of 0.85 kPa of water, the species should be transformed thoroughly into polymerized species at 290 K whereas reverse transformation to monooxo (distorted) tetrahedral vanadate was observed at 473 K. This temperature dependence of V site structure in moisture was consistent with literature based on Raman spectroscopy.$^{46}$ Dissociative adsorption of 2-propanol to the dispersed vanadate was suggested to constitute (nearly) octahedral V sites at 290–473 K. This was consistent with literature where different reactivities of the V–O–M (M = Si, Al, and Ti) bond with ethanol were discussed based on Raman spectroscopy.$^{49}$ As far as our V+/TiO$_2$ samples were preheated to 473 K in air, the V$^{V}$ site structures seem to be common for V/TiO$_2$, V/mesoporous TiO$_2$, and sol–gel V–TiO$_2$. An exception was the V$^{IV}$ species dominant for mesoporous V–TiO$_2$. The V sites substituted on the Ti sites of high-surface-area TiO$_2$.

**Acknowledgment.** The XAFS experiments were performed under the approval of the Photon Factory Proposal Review Committee (2001G308 and 2002G285) and under the approval of the SPring-8 Program Review Committee and the National Institute for Materials Research as Nanotechnology Support Project of the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) (2003A0146-NX-np and 2002B0739-NX-np). The authors are thankful for financial support from the Grant-in-Aid for Scientific Research from MEXT (B1355 5230), Yamada Science Foundation (2000), and Toray Science Foundation (98-3901).
